## Abstract

In this SOP, the principle of operation of integration through Monte Carlo will be discussed. Certain issues and design considerations will also be explored.

# 1 Description of Monte Carlo

Monte Carlo Integration is a technique which can be applied to quantum field theory, dynamical systems of particles, and Finite Element Analysis. [1]

The major types of Monte Carlo integration are uniform sampling, stratified sampling, sequential Monte Carlo, and mean field particle methods. Consider the fundamental theorem of Calculus:

**Theorem 1.**

$$F(x) = \int_a^b f(x) dx$$

By choosing a random value  $x$  constrained by  $a$  and  $b$  and multiplying by the difference  $(b-a)$ , this approximates a single rectangle with area of  $x(b-a)$ . Adding up these rectangles approximates the area under  $f(x)$  like a Riemann Sum with a random distribution. Hence, the general formula is

$$I = \frac{b-a}{N} \sum_{i=0}^N f(x_i).$$

[2] Uniform sampling samples a uniform probability distribution is one where there is an equal probability for all numbers within . Stratified sampling divides the total space into smaller groups rather than uniform distribution.

## 2 Error of Monte Carlo

The error of such an integration is evidently important for such a method. This can be quantified using the variance ( $\sigma$ ) or alternatively the standard error of the mean which is calculated by  $\frac{\sigma}{\sqrt{N}}$  due to the central limit theorem. [3]

## 3 Numerically Solving with Monte Carlo Integration

Example: Let the equation  $f(x) = 5x^2 + 2x$ . Find the area under the curve from -2 to 7 using Monte Carlo integration.

In this case, we need to import *random* to assign uniform probability distribution. There are better ways to generate random numbers as the algorithm by scipy is deterministic however they are beyond the scope of this tutorial.

```
from scipy import random
import numpy as np
import matplotlib.pyplot as plt
```

Next, we need to define the bounds of integration as well as the sample size

```
a=-2
b=7
N=10000
xrandom=np.zeros(N)
```

Finally, define the target function listed above and iterate through the sample size while multiplying by the formula  $(b-a)/n$ .

```
def f(x):
    return 5*x**2+2*x

integral=0.0
for i in range(N):
    integral+=f(xrandom[i])

answer=(b-a)/float(N)*integral
print(answer)
```
